`dlsem` version 1.3.1 – September 16, 2016.

Contents

1 Introduction

Package `dlsem` implements estimation and path analysis functionalities for structural equation modelling with second-order polynomial lag shapes [7]. Structural equation modelling is of great interest in econometric problems, as they allow to perform path analysis, that is the decomposition of the causal effect of any variable on another. Second-order polynomial lag shapes were introduced by [7] in order to account for temporal delays in the dependence relationships among the variables. Second-order polynomial lag shapes have several advantages, including simplicity of estimation, and a clear interpretation of parameters for domain experts, so that prior knowledge can be taken into account in statistical analyses by introducing simple mathematical constraints.

In this vignette, theory on structural equation modelling with second-order polynomial lag shapes is summarized in Section 2, then the practical use of `dlsem` is illustrated in Section 3. Concluding remarks are pointed out in Section 4.

2 Theory

The basic feature of SEM is a directed acyclic graph (DAG). In a DAG, variables are represented by nodes and directed edges may connect pairs of variables without creating directed cycles (See Figure 1). If a variable receives an edge from another variable, the latter is called *parent* of the

former. A DAG encodes a factorization of the joint probability distribution:

$$p(V_1, \ldots, V_m) = \prod_{j=1}^{J} p(V_j \mid \Pi_j) \tag{1}$$

where Π_j is the set of parents of variable V_j. As such, if some pairs of variables are not connected by an edge, the DAG implies a set of conditional independence statements [6]. The DAG may eventually have a causal interpretation. If this is the case, edges represent direct causal relationships. SEM is implemented by simultaneously applying linear regression models:

$$\begin{cases} V_1 = f_1(\Pi_1) \\ \ldots \\ V_j = f_j(\Pi_j) \\ \ldots \\ V_m = f_m(\Pi_m) \end{cases} \tag{2}$$

where $V_j = f_j(\Pi_j)$ is the equation describing the linear regression model where V_j is the response variable and its parents in the DAG are the covariates. A comprehensive review of SEM can be found in [5].

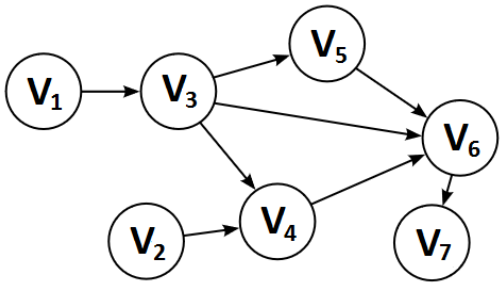

Figure 1: A directed acyclic graph.

SEM can be employed to perform path analysis, that is the decomposition of the causal effect of any variable on another. Path analysis in SEM must follow some tracing rules developed by [9] (see also [8]):

- the causal effect associated to each edge in the DAG is represented by the coefficient of the variable originating the edge in the regression model of the variable receiving the edge;
- the causal effect associated to a directed path is represented by the product of the causal effects associated to each edge in the path;
- the causal effect of a variable on another is represented by the sum of the causal effects associated to each directed path connecting the two variables.

Often, the causal effect of a variable on another is termed *overall* causal effect, the causal effect associated to a directed path made by a single edge is called *direct* effect, while the causal effects associated to the other directed paths are denoted as *indirect* effects.

Distributed-lag linear regression is an extension of the classic linear model including lagged instances of one or more quantitative covariates:

$$y_t = \beta_0 + \sum_{j=1}^{J} \sum_{l=0}^{L_j} \beta_{j,l}\ x_{j,t-l} + \epsilon_t \qquad \epsilon_t \sim \mathrm{N}(0, \sigma^2) \tag{3}$$

where y_t is the value of the response variable at time t and $x_{j,t-l}$ is the value of the j-th covariate at l time lags before t. The set $(\beta_{j,0}, \beta_{j,1}, \ldots, \beta_{j,L_j})$ is denoted as the *lag shape* of the j-th covariate and represents its effect on the response variable at different time lags. Estimation of a distributed-lag linear regression model using ordinary least squares is inefficient because lagged instances of the same covariate are typically highly correlated. Also, the lag shape of a covariate is completely unrestricted, thus problems of interpretation may arise.

Second-order polynomial lag shapes can be used to solve these drawbacks [1, Chapter 6]. They include the endpoint-constrained quadratic lag shape:

$$\beta_{j,l} = \begin{cases} \theta_j \left[-\frac{4}{(b_j - a_j + 2)^2} l^2 + \frac{4(a_j + b_j)}{(b_j - a_j + 2)^2} l - \frac{4(a_j - 1)(b_j + 1)}{(b_j - a_j + 2)^2} \right] & a_j \leq l \leq b_j \\ 0 & \text{otherwise} \end{cases} \tag{4}$$

and the quadratic decreasing lag shape:

$$\beta_{j,l} = \begin{cases} \theta_j \frac{l^2 - 2 b_j l + b_j^2}{(b_j - a_j)^2} & a_j \leq l \leq b_j \\ 0 & \text{otherwise} \end{cases} \tag{5}$$

(see Figure 2). The endpoint-constrained quadratic lag shape is zero for a lag $l \leq a_j - 1$ or $l \geq b_j + 1$, and symmetric with mode equal to θ_j at $(a_j + b_j)/2$. The quadratic decreasing lag shape decreases from value θ_j at lag a_j to value 0 at lag b_j according to a quadratic function. Value a_j is denoted as the *gestation lag*, and value $b_j - a_j$ as the *lag width*. A second-order polynomial lag shape is monotonic in the sign, that is $\beta_{j,l}$ is either non-negative or non-positive for any j and l.

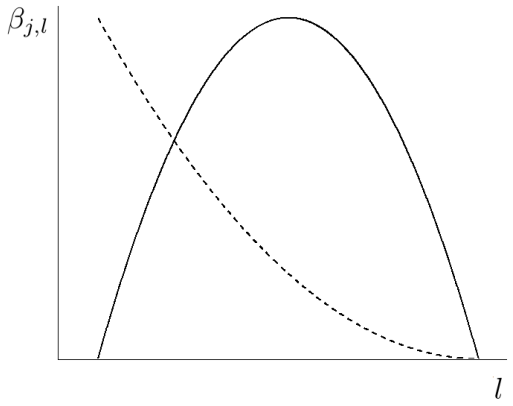

Figure 2: Second-order polynomial lag shapes: endpoint-constrained quadratic lag shape (straight line), quadrating decreasing lag shape (dotted line).

A distributed-lag linear regression model with second-order polynomial lag shapes is linear in parameters θ_j $(j = 1, \ldots, J)$, provided that parameters a_j and b_j $(j = 1, \ldots, J)$ are known. Thus, one can use ordinary least squares to estimate the parameters of several models where the value of a_j and b_j is varied within a grid of values, and then select the model with the lowest value of the Akaike Information Criterion [1].

Distributed-lag structural equation modelling (DLSEM) is an extension of SEM, where variables are related by distributed-lag linear regression models with second-order polynomial lag shapes [7]. In DLSEM, the DAG does not explicitly include time lags but a special semantic holds:

[1] Neither the response variable nor the covariates must contain a trend in order to obtain unbiased estimates [4]. A reasonable procedure is to sequentially apply differentiation to all variables until the Dickey-Fuller test rejects the hypothesis of unit root for all of them.

- if an edge connects two variables, there is at least one time lag where the coefficient of the variable originating the edge in the regression model of the variable receiving the edge is non-zero.

As a consequence, an edge of the DAG is considered as statistically significant if there is at least one time lag where the estimate of the coefficient of the variable originating the edge in the regression model of the variable receiving the edge is statistically significant.

DLSEM can be employed to perform path analysis at different time lags by extending tracing rules for SEM:

- The causal effect associated to each edge in the DAG at lag k is represented by the coefficient at lag k of the variable originating the edge in the regression model of the variable receiving the edge.
- The causal effect associated to a directed path at lag k is computed as follows:
  1. denote the number of edges in the path as p;
  2. enumerate all the possible p-uples of lags, one lag for each of the p edges, such that their sum is equal to k;
  3. for each p-uple of lags:
     - for each lag in the p-uple, compute the coefficient associated to the corresponding edge at that lag;
     - compute the product of all these coefficients;
  4. sum all these products.
- The causal effect of a variable on another at lag k is represented by the sum of the causal effects at lag k associated to each directed path connecting the two variables.

A causal effect evaluated at a single lag is denoted as *instantaneous* causal effect. The *cumulative* causal effect at a prespecified lag, say k, is obtained by summing all the instantaneous causal effects for each lag up to k.

3 Distributed-lag structural equation modelling with dlsem

The practical use of package `dlsem` is illustrated by an application to a simplified impact assessment problem inspired by the empirical analysis in [2]: to test whether the influence through time of the registration of agricultural patent applications (proxy of the technological innovation in Agriculture) on the benefits of farmers and consumers (here measured by the net entrepreneurial income index and the price index of agricultural products, respectively) is direct and/or mediated by the gross value added of the agricultural sector. The analysis will be conducted on the dataset `agres`, containing data for 10 European countries (Austria, Germany, Spain, Finland, France, Ireland, Italy, Netherlands, Sweden, United Kingdom) in the period 1990-2010 from the EUROSTAT database (`http://ec.europa.eu/eurostat/data/database`).

The DAG corresponding to the research question is shown in Figure 3.

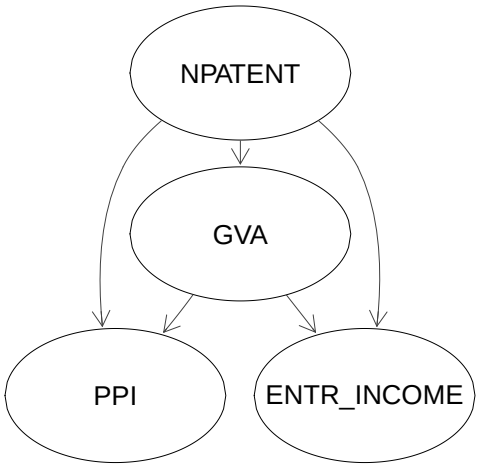

Figure 3: The DAG addressing the research question inspired by the empirical analysis in [2]. 'NPATENT': number of agricultural patent applications. 'GVA': gross value added of the agricultural sector. 'ENTR_INCOME': net entrepreneurial income index. 'PPI': price index of agricultural products.

3.1 The model code

The first step is the specification of the model code containing the hypothesized DAG and the lag shapes. The model code must be a list of formulas, one for each regression model. In each formula, the response and the covariates must be quantitative variables and operators quec( ) and qdec( ) can be employed to specify, respectively, an endpoint-constrained quadratic or a quadratic decreasing lag shape. Each of these operators has three arguments: the name of the variable to which the lag shape is applied, the minimum lag with a non-zero coefficient (a_j), and the maximum lag with a non-zero coefficient (b_j). If none of these two operators is applied to a variable, it is assumed that the coefficient associated to that variable is 0 for time lags greater than 0 (no lag). The group factor and exogenous variables must not be specified in the model code (see Subsection 3.3). The regression model for variables with no parents besides the group factor and exogenous variables can be omitted from the model code. In this illustration, an endpoint-constrained quadratic lag shape between 0 and 15 time lags is assumed for all variables:

```
> mycode <- list(
+   GVA~quec(NPATENT,0,15),
+   PPI~quec(NPATENT,0,15)+quec(GVA,0,15),
+   ENTR_INCOME~quec(NPATENT,0,15)+quec(GVA,0,15)
+   )
```

3.2 Control options

The second step is the specification of control options. Control options must be a named list containing one or more among several components. The key component is adapt, a named vector of logical values where each value must refer to one response variable and indicates whether values a_j and b_j for each lag shape in the regression model of that variable must be selected on the basis of the best fit to data, instead of employing the ones specified in the model code. If adaption is requested for a regression model, three further components are taken into account: max.gestation, min.width and sign. Each of these three components is a named list, where each component of the list must refer to one response variable and must be a named vector including, respectively, the maximum gestation lag, the minimum lag width and the sign (either '+' for non-negative, or '-' for non-positive) of the coefficients of one or more covariates. In this illustration, adaptation of lag shapes is performed for all regression models with the following constraints: (i) maximum gestation lag of 3 years, (ii) minimum lag width of 5 years, (iii) all coefficients with non-negative sign, excepting the ones in the regression model of the price index of agricultural products, as benefits for consumers improve with the decreasing of prices:

```
> mycontrol <- list(
+   adapt=c(GVA=T,PPI=T,ENTR_INCOME=T),
+   max.gestation=list(GVA=c(NPATENT=3),PPI=c(NPATENT=3,GVA=3),
+     ENTR_INCOME=c(NPATENT=3,GVA=3)),
+   min.width=list(GVA=c(NPATENT=5),PPI=c(NPATENT=5,GVA=5),
+     ENTR_INCOME=c(NPATENT=5,GVA=5)),
+   sign=list(GVA=c(NPATENT="+"),PPI=c(NPATENT="-",GVA="-"),
+     ENTR_INCOME=c(NPATENT="+",GVA="+"))
+   )
```

3.3 Estimation

Once the model code and control options are specified, the structural model can be estimated from data using the command dlsem( ). The user can indicate a group factor to argument group and one or more exogenous variables to argument exogenous. By indicating the group factor, one intercept for each level of the group factor will be estimated in each regression model. By indicating exogenous variables, they will be included as non-lagged covariates in each regression model, in order to eliminate spurious effects due to differences between the levels of the group factor. Each exogenous variable can be either qualitative or quantitative and its coefficient in each regression model is 0 for time lags greater than 0 (no lag). Furthermore, the user can decide to perform any number of the following operations:

- differentiation until the hypothesis of unit root is rejected by the Dickey-Fuller test for all the quantitative variables (by setting argument uniroot.check to TRUE);
- imputation of missing values for quantitative variables using the Expectation-Maximization algorithm [3] (by setting argument imputation to TRUE);
- apply the logarithmic transformation to all quantitative variables in order to interpret each coefficient as an elasticity (by setting argument log to TRUE).

In this illustration, the country is indicated as the group factor, gross domestic product and average farm size as exogenous variables, differentiation until stationarity, imputation of missing values and logarithmic transformation is allowed for all quantitative variables:

```
> mod0 <- dlsem(mycode,group="COUNTRY",exogenous=c("GDP","FARM_SIZE"),
+   data=agres,control=mycontrol,uniroot.check=T,imputation=T,log=T)
Checking stationarity...
 Order 1 differentiation performed
```

```

 Estimating regression model 4/4 (ENTR_INCOME)
Estimation completed
```

After estimating the structural model, the user can display the DAG including only statistically significant edges.

```
> plot(mod0)
```

The result is shown in Figure 4: each edge is coloured according to the sign of its causal effect (green for non-negative, red for non-positive), while the group factor and exogenous variables are omitted from the DAG.

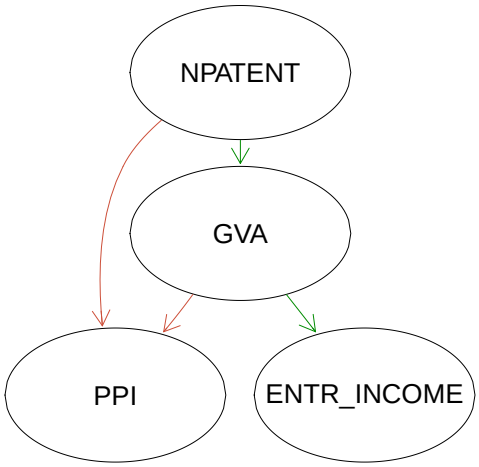

Figure 4: The DAG including only statistically significant edges. Green: non-negative causal effect. Red: non-positive causal effect.

All edges result statistically significant, excepting the one of the number of agricultural patent applications on the net entrepreneurial income index. This provides evidence that the effect of technological innovation on the benefits for consumers is both direct and mediated by the gross value added of Agriculture, and the effect of the effect of technological innovation on the benefits for farmers is only mediated by the gross value added of Agriculture.

The user can also request the summary of estimation:

```
> summary(mod0)

The summary of estimation returns estimates of parameters θ_j $(j = 1, \ldots, J)$. Instead, the command edgeCoeff( ) can be used to obtain estimates and confidence intervals of coefficients at the relevant time lags $\beta_{j,l}$ $(j = 1, \ldots, J;\ l = 0, 1, \ldots)$:

```
> edgeCoeff(mod0)

Coefficients in the regression model of the price index of agricultural products are all of negative sign because benefits for consumers improve with the decreasing of prices.

3.4 Path analysis

Path analysis can be performed using the command pathAnal( ). The user must specify one or more starting variables (argument from) and the ending variable (argument to). Optionally, specific time lags on which path analysis should be focused can be provided to argument lag, otherwise all the relevant ones are considered. Also, the user can choose whether instantaneous (argument cumul set to FALSE, the default) or cumulative (argument cumul set to TRUE) causal effects must be returned. Here, two path analysis tasks are performed: one from agricultural patent applications to the net entrepreneurial income index, and the other from agricultural patent applications to the price index of agricultural products. For both, time lags 5, 10, 15, 20 and 25 are considered, and cumulative causal effects are requested:

```
> pathAnal(mod0,from="NPATENT",to="ENTR_INCOME",lag=c(5,10,15,20,25),cumul=T)
$`NPATENT*GVA*ENTR_INCOME`
         2.5%       50%     97.5%

```

The output of path analysis is a list of matrices, each containing estimates and confidence intervals of the causal effect associated to each path connecting the starting variables to the ending variable at the requested time lags. Also, estimates and confidence intervals of the overall causal effect is shown in the component named overall.

Since the logarithmic trasformation was applied to all quantitative variables, causal effects above are interpreted as elasticities, that is, for a 1% of patent applications more, benefits for farmers and consumers are expected to grow by 6.7% and 1.8%, respectively, after 30 years.

The estimated lag shape associated to an overall causal effect can be displayed using the command lagPlot( ):

```
> lagPlot(mod0,from="NPATENT",to="ENTR_INCOME")
> lagPlot(mod0,from="NPATENT",to="PPI")
```

The result is shown in Figure 5.

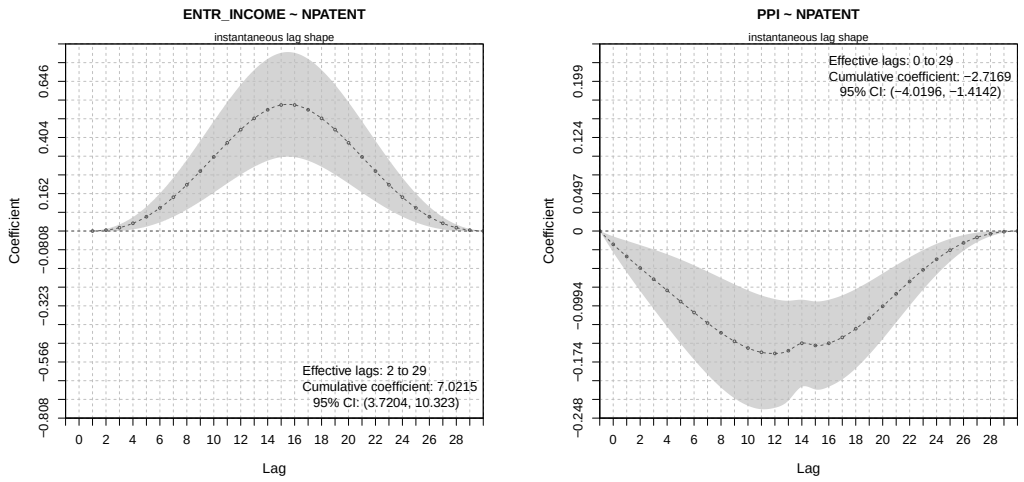

Figure 5: The estimated lag shape associated to the overall causal effect of agricultural patent applications on the net entrepreneurial income index and the price index of agricultural products. 95% confidence intervals are shown in grey.

4 Concluding remarks

Package `dlsem` is conceived to perform impact analysis, that is the quantitative assessment of the consequences on a system due to an internal or external impulse, using distributed-lag structural equation modelling with second-order polynomial lag shapes.

Impact analysis is widely employed in econometrics, where temporal attribution is a debated problem. In particular, there is no consensus on the formal specification of lag relationships to be applied in a certain problem domain. Second-order polynomial lag shapes are a flexible solution,

as they are simple to be estimated, and the interpretation of parameters is clear for domain experts, thus prior knowledge can be taken into account in statistical analyses by introducing simple mathematical constraints.
